## GUIDE

Models for time evolution in activity at a voxel

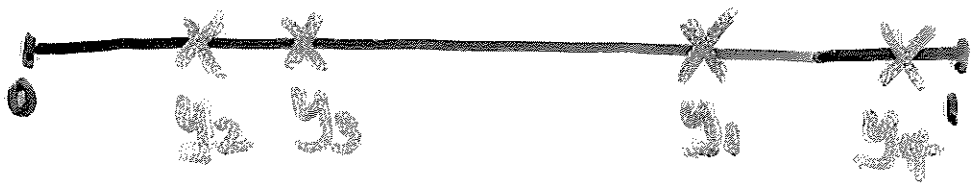

Reconstruction method    ( *dynamics parameters* )

Evaluation by simulation

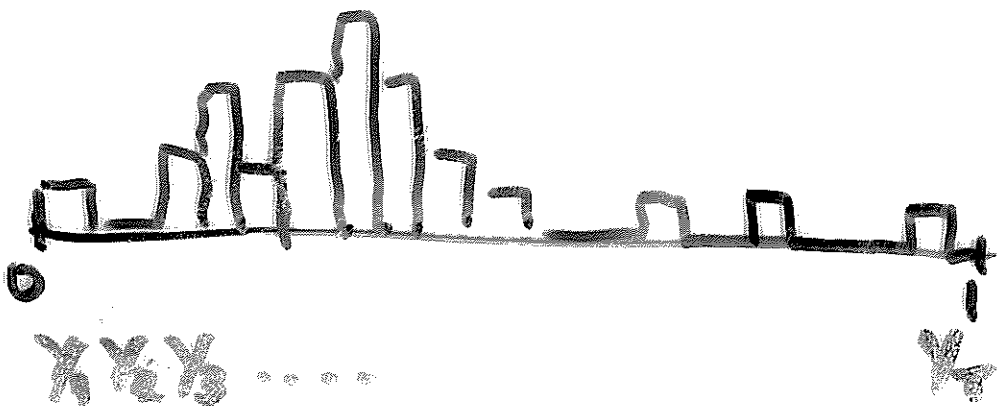

# Data Representation

(observations in range 0-1)

## I. $n$ observations

## II. Digitised data : (binned)

## CONTEXT

Medical image SPECT - dynamics!

*As in earlier talks  
Earlier talks have  
highlighted again opportunities  
for statisticians to model*

*Introduction of radioisotope into bloodstream, In this case as SPECT  
uptake in imaged body region (delay voxel specific)  
scintillation events recorded in a sequence of time slices.*

\* *Aim is to <sup>estimate</sup> evaluate dynamic parameters (key to functioning of  
Our approach involves reconstruction: body not anatomy)*

at every point (voxel) within the body region  
from a time series of (activity) counts  
mixture model parameter estimation (voxel  
specific)

Evaluation - desirable properties

interpretable  
*failsafe*  
fast computation  
efficient

## CONTEXT

Medical image SPECT - dynamics!

*Introduction* of radioisotope into bloodstream,  
*uptake* in imaged body region (delay voxel specific)  
scintillation *events* recorded in a sequence of time slices.

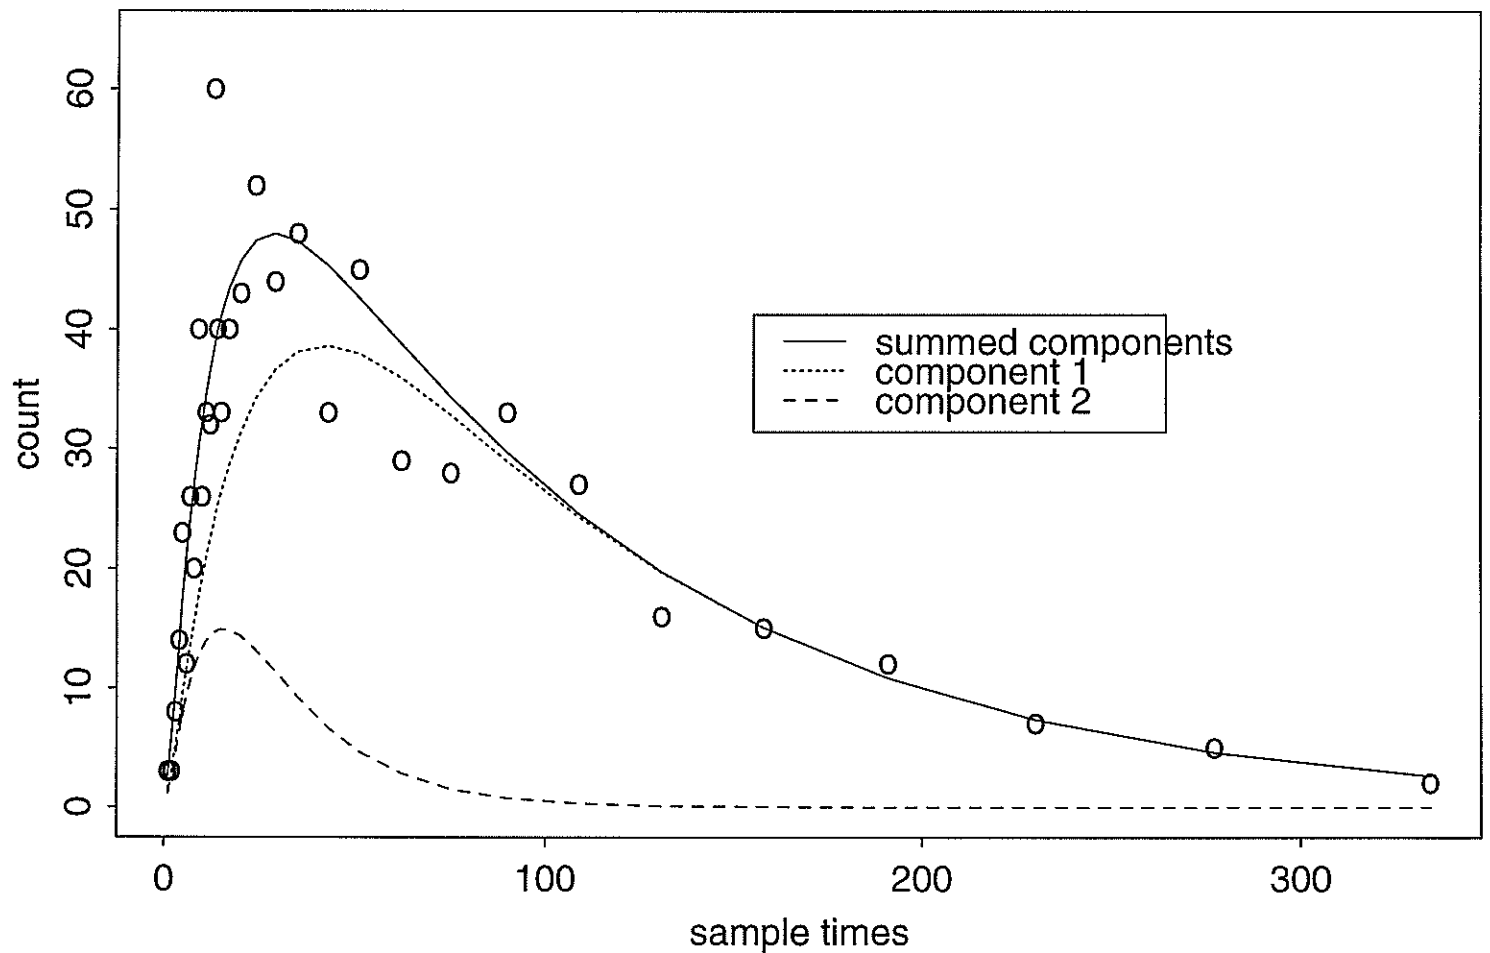

Our approach involves reconstruction:

at every point (voxel) within the body region  
from a time series of (activity) counts  
mixture model parameter estimation (voxel  
specific)

Evaluation - desirable properties

interpretable  
*failsafe*  
fast computation  
efficient

# Count data and components of the distribution

NOTE : 32 observations , each a count.

*TACs*

Snyder (1984), Cunningham & Jones (1993)

Compartmental models parameterize  $f_j$ , involving a *mixture model* for the expected number of events:

$$\lambda_{jt} = f_j(t) = \sum_{k=1}^K \beta_{jk} x_k(t)$$

where

$$x_k(t) = x_0(t) \otimes (1/\sigma_k) \exp(-t/\sigma_k)$$

$\beta_k$ - weights of the  $K$  modes

$x_0(t)$  - known input function

Fitting parameters:

- EM algorithm for Maximum Likelihood (ML)
- Quadratic programming for Weighted Least Squares (WLS) subject to constraints

Approach:

Linear model for *digitised* event times.

Resulting model:

independent Poisson counts  $Y_1, \dots, Y_T$  with vector of expected values

$$EY = \lambda = X\beta$$

where  $X$  is a *known*  $T \times K$  matrix,  $\beta$  is a  $K \times 1$  vector proportional to the mixing probabilities.

Non-zero  $\beta$ -coefficients correspond to modes present in the data: each column of  $X$  is the TAC for one particular *mode*.

## Quadratic Programming

Minimize

$$S(\beta) = \sum_1^T w_i (Y_i - \mu_i(\beta))^2$$

where

$$\mu_i(\beta) = \lambda_i = x_i^T \beta$$

$w_1, \dots, w_T$  are weights fixed in advance.

The minimum is found subject to *constraints*  $\beta_k \geq 0$ .

*Active constraints* are those parameters  $\beta_k$  set to zero.

The corresponding modes (components of the mixture) are absent.

*Implementation:* Gill & Murray, NNLS

SKIP ?

*How does convolution arise?*

## I. Errors in measurements

Model

$$y = x + z$$

Observables

1. We record independent sample observations  $y_1, \dots, y_n$ , where
2. error distribution is known (e.g. normal distribution)

Objective is to reconstruct the d.f. of  $x$  (non parametric formulation).

## II. Delayed or blurred signals

~~here we will take a semi-parametric~~  
~~formulation~~

## SIMULATION DESCRIPTION

Event activity distribution the mixture of 2 components.

Sequences of 32 corresponding bin counts, *logarithmic* spacing.

Variables:

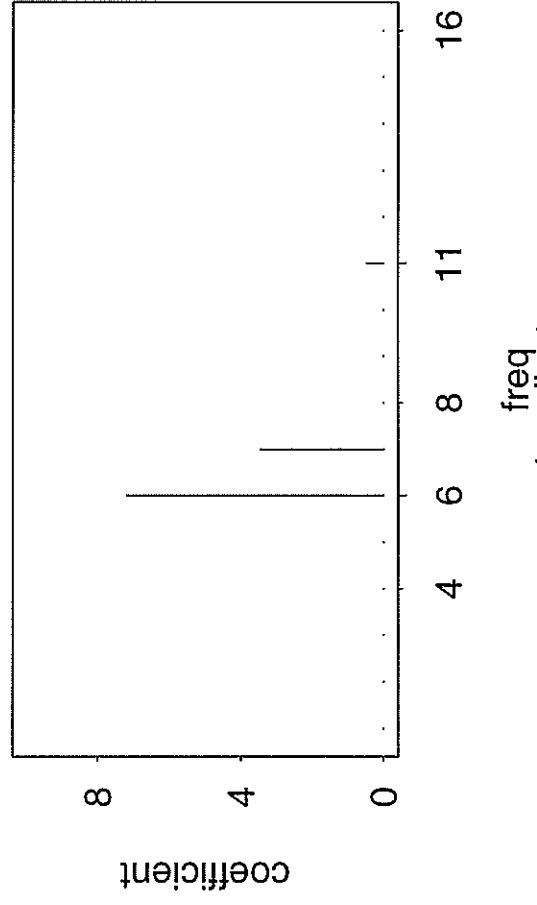

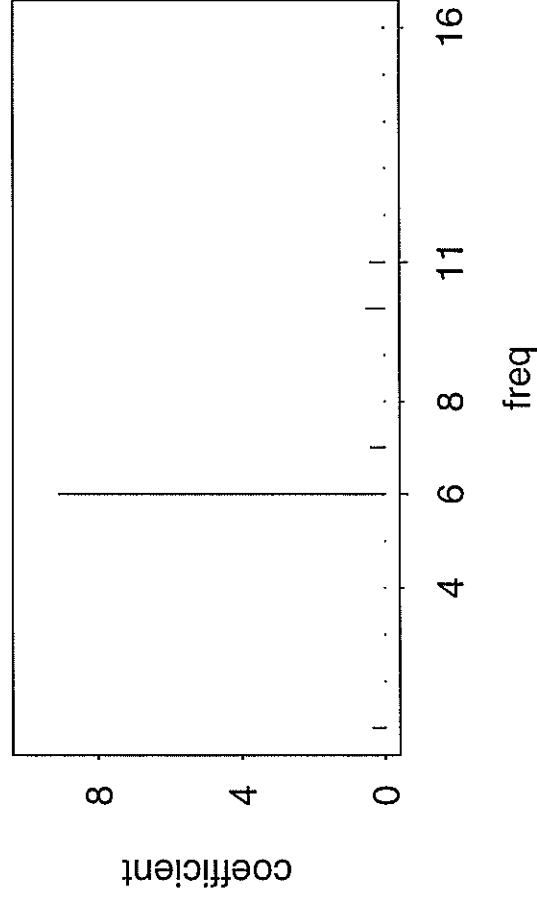

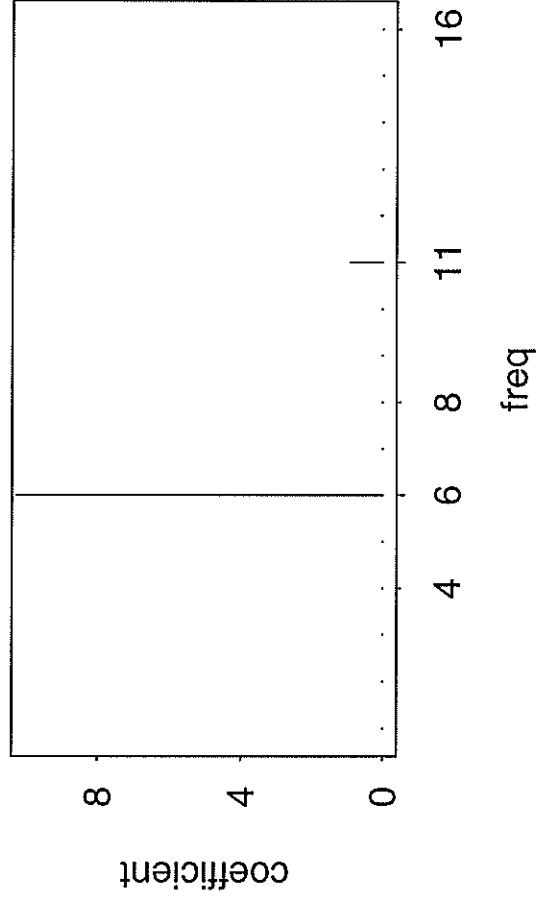

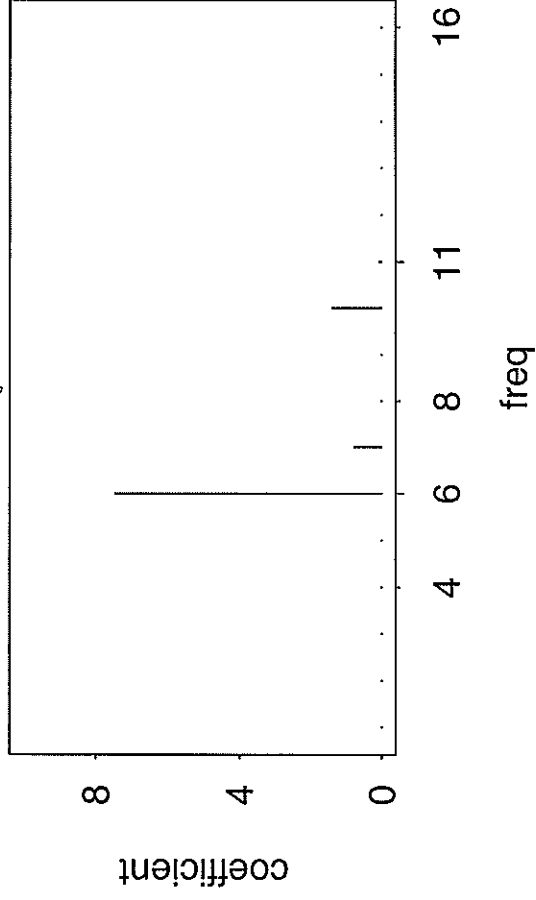

*sample size: small/ large*      *for a single voxel* <sup>*in SPECT*</sup> *(not aggregated*  
*mix of high and low frequency delays: 10: 1 and ROI)*  
 1:10

*reconstruction approach*

- basis dimension ( $K=16/64$ )      *remember 32 observations!*
- variance estimate (true/ data)
- ridge adjustment constant

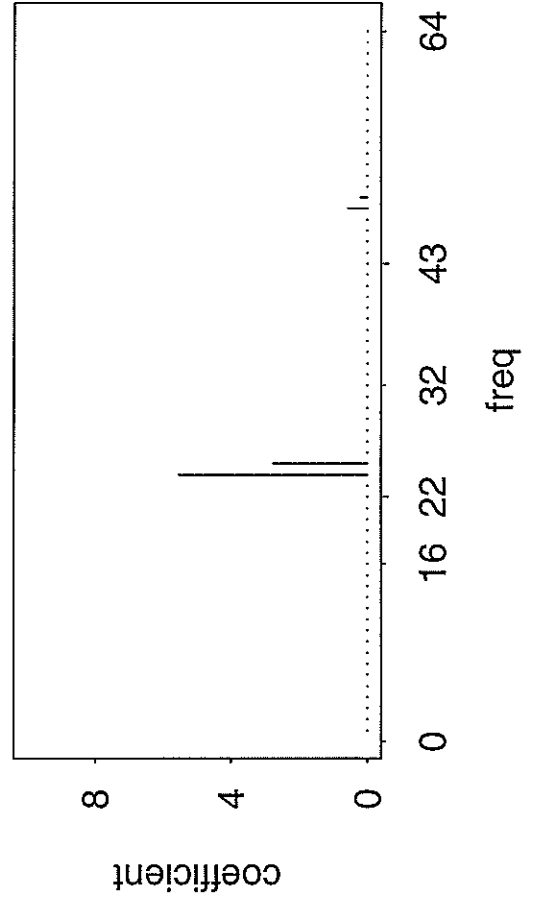

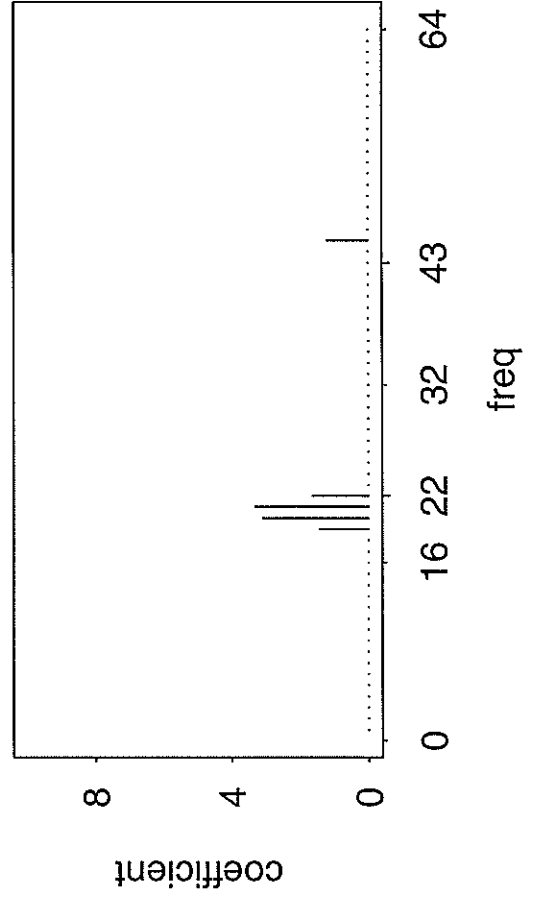

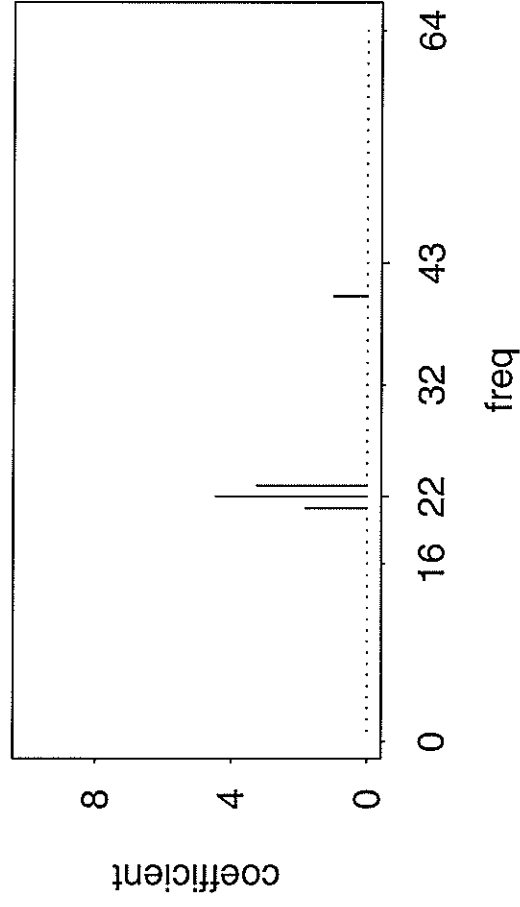

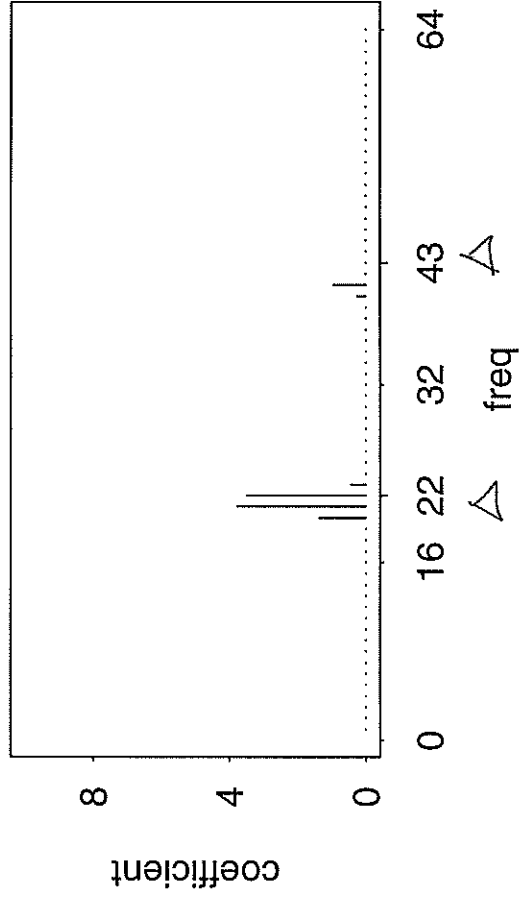

# Coefficients: emprirical weights, N=32

\* 1/6  
\*  $\beta_{\text{price}}$   
\*  $\beta_{\text{selection}}$

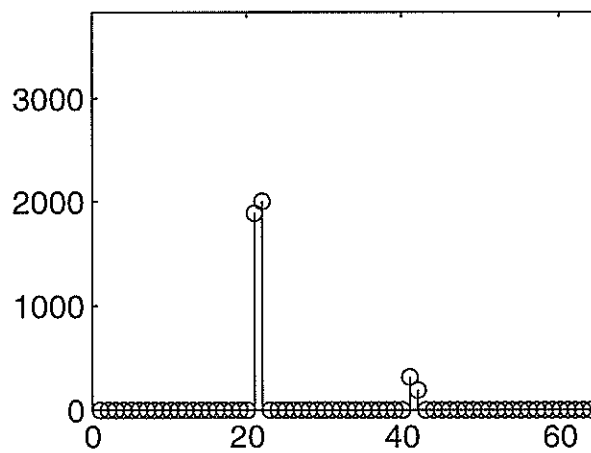

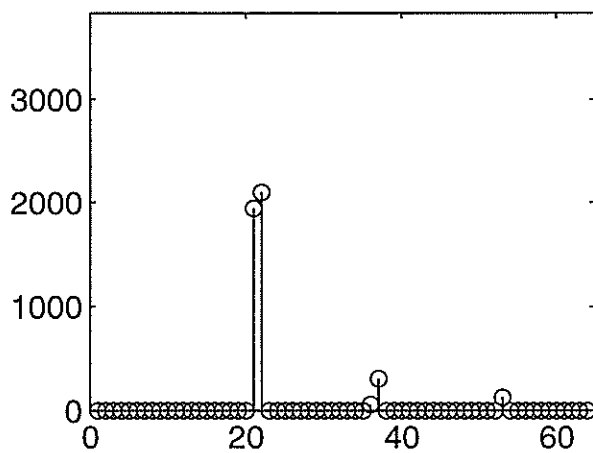

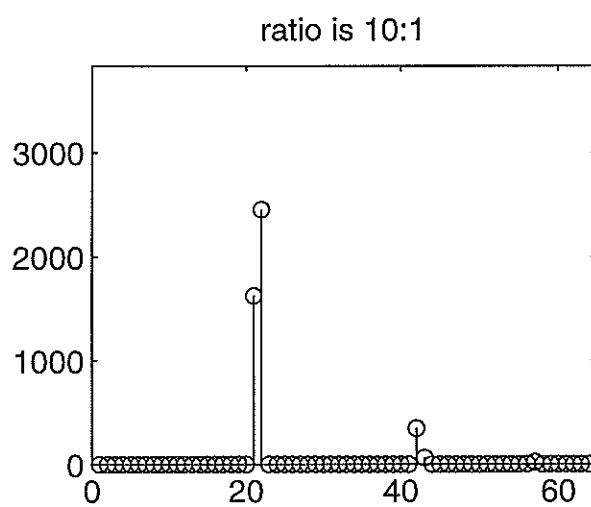

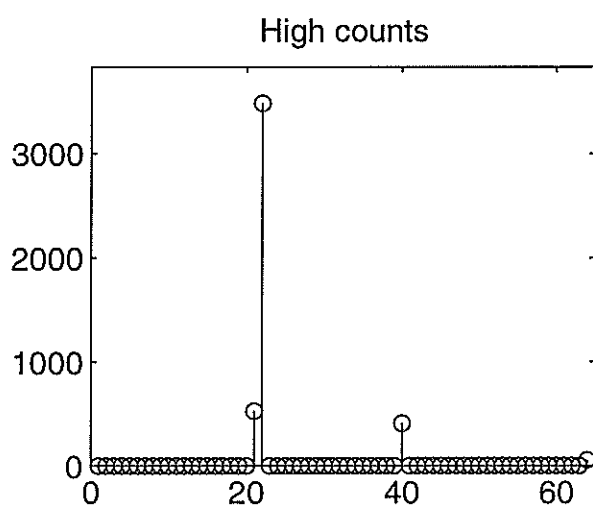

4 replicates, high wise

Note sparse representation, selection of ~~best~~<sup>most</sup> components

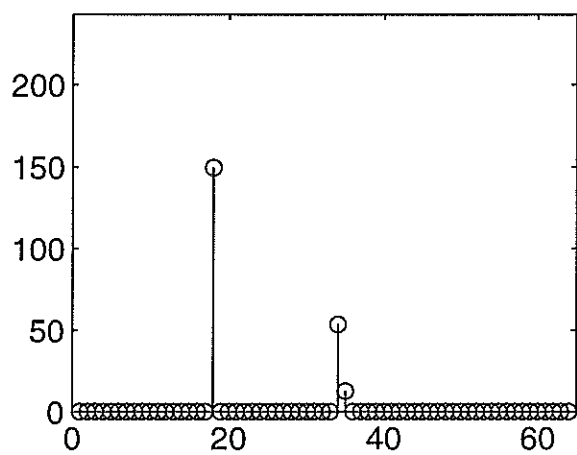

\* NNLS

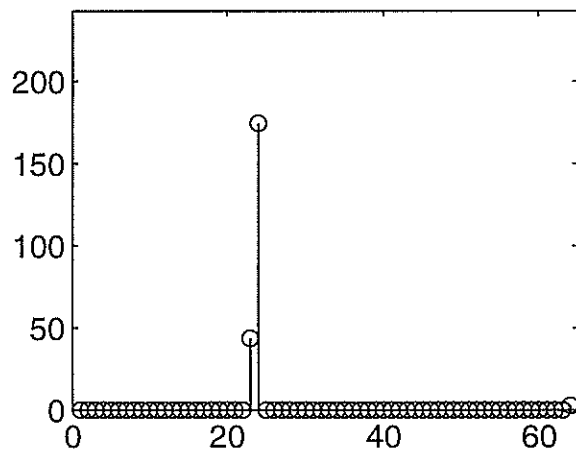

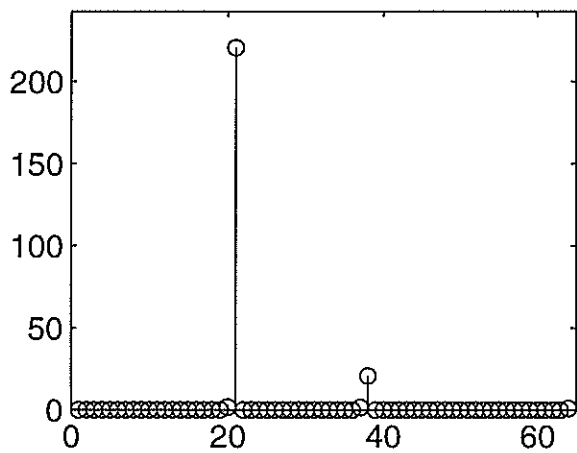

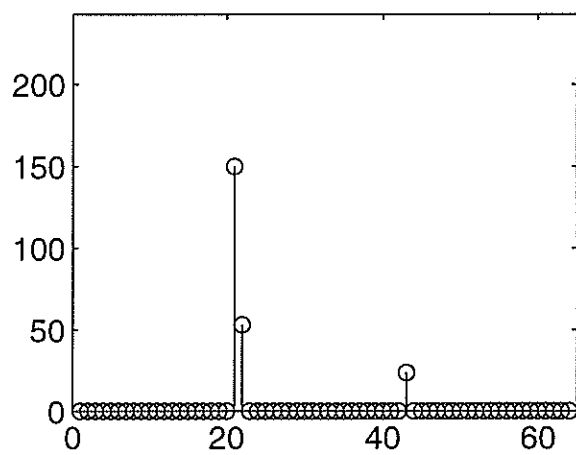

\* Stability of high count results

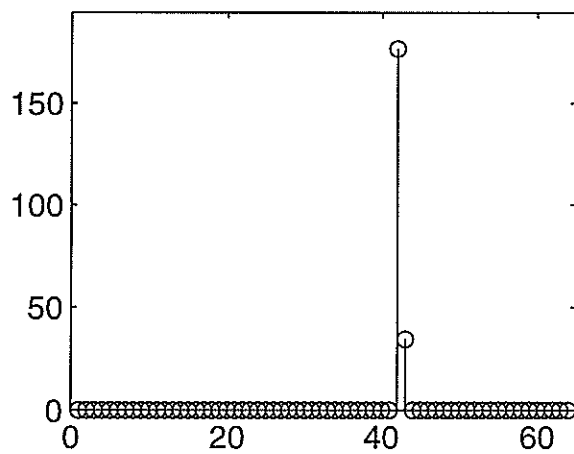

Low counts

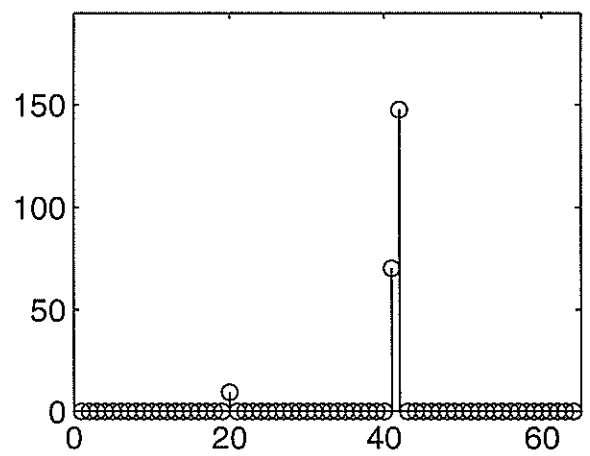

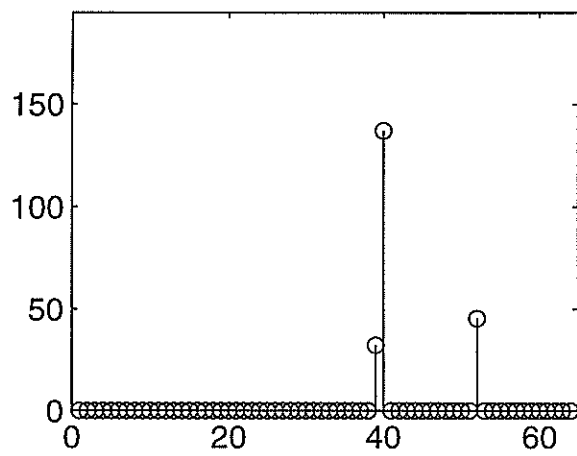

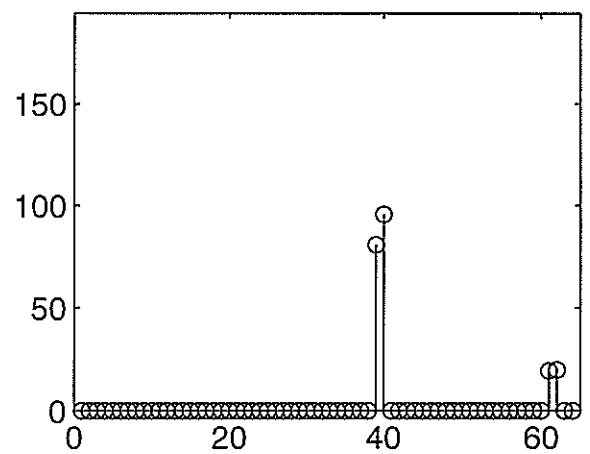

ratio is 10:1

\* Low counts

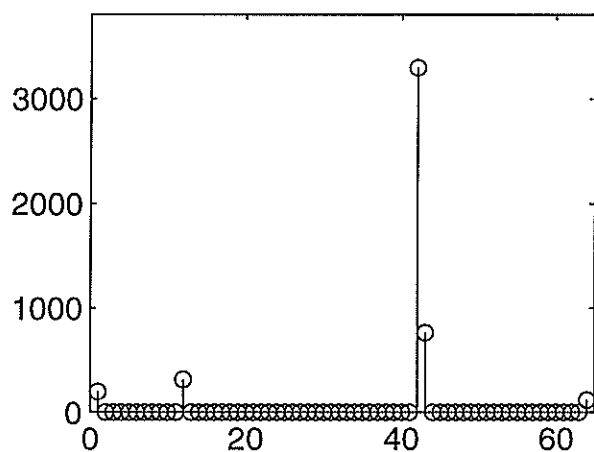

ratio is 1:10

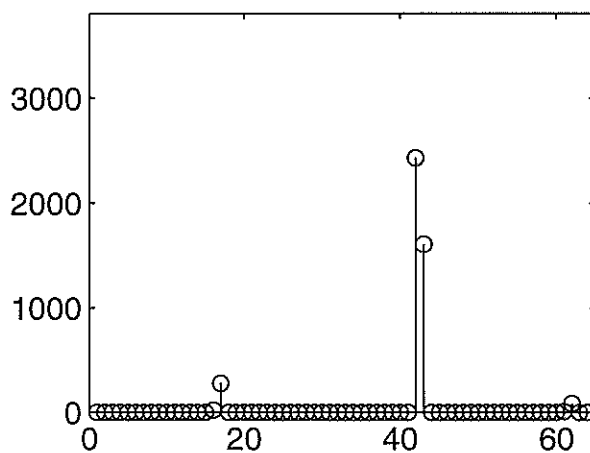

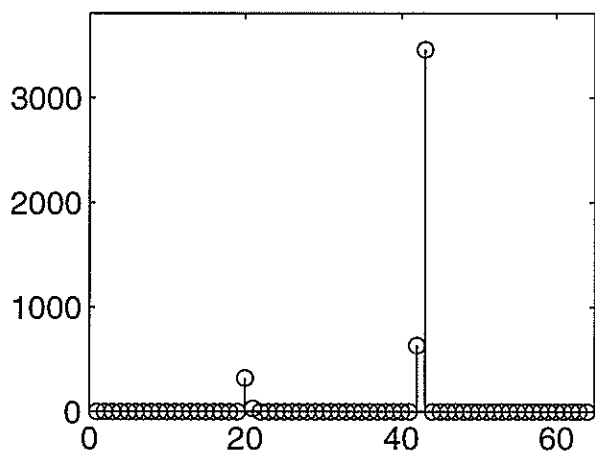

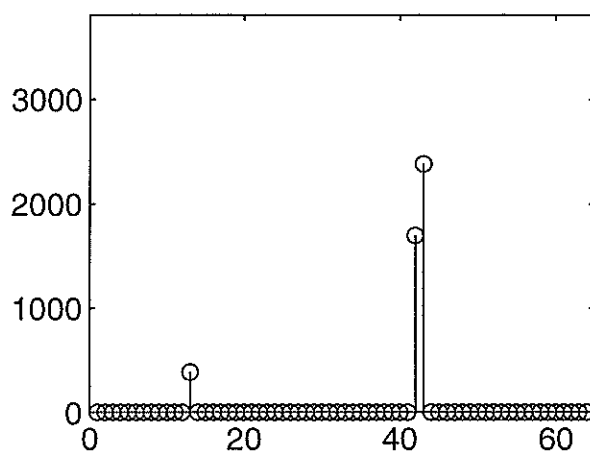

When High frequency predominant ~~in~~  
\* accurate results

High counts

ratio is 1:10

## Review:

- a multiple mode model was fitted to find different components of delay to a signal;
- we empirically determine the probabilities of modes (indexed by  $k$ ); *selecting amongst a dense basis*
- ridge regression is effective in reducing high frequency artefacts.

## Some observations/ extensions:

- convergence of the algorithm can be assessed by *leakage*;
- QP algorithm is faster than EM, but uses WLS (not ML), with weights affected by data variability;
- this doesn't seem to matter;
- *Exploratory tool —* multiple images result; overspecify then postprocess by spatial and/or ~~frequency~~ *temporal* smoothing?
- following ML-EM reconstruction from *projections*, the Poisson space-time process is *NOT* a naive assumption.
